# Extreme precipitation events in NW Greece

E. E. Houssos and A. Bartzokas

Laboratory of Meteorology, Department of Physics, University of Ioannina, Greece

Received: 31 October 2005 – Revised: 9 December 2005 – Accepted: 16 December 2005 – Published: 2 February 2006

**Abstract.** In this work, the extreme precipitation events in NW Greece are studied. The data used are daily precipitation totals recorded at the meteorological station of Ioannina University for the period 1970–2002. 156 days with precipitation totals above 35 mm (5% upper limit) are only considered. It is seen that, a minimum frequency of extreme precipitation events appears in the period 1986–1991, which is characterized by a high positive NAO index. For each of the 156 extreme precipitation days, at first, the mean sea level pressure pattern over Europe is constructed by using 273 grid point values. Using Factor Analysis, the dimensionality of the  $156 \times 273$  data matrix is reduced to  $156 \times 5$  (84% of the total variance) and then, Cluster Analysis is applied on the results of Factor Analysis. Thus, the 156 cases are grouped objectively to 11 clusters, revealing the main pressure patterns, which favour extreme precipitation in NW Greece. Seven of the patterns are encountered in winter and autumn, while three of them cover a period from autumn to spring and one appears mainly in summer. In all of them the cause of the extreme precipitation event is a low pressure system centred west of Greece or a low pressure trough extended eastwards or southwards up to Greece. In some cases the depression is so strong and extended that it covers the whole Europe and the Mediterranean. In the single summer pattern, rainfall is caused by an extension of the SW Asia thermal low up to the central Mediterranean.

## 1 Introduction

Research on climate change in Europe and the Mediterranean has attracted the interest of many scientists during recent decades. Most of them are focused on temperature changes only (see e.g. Metaxas et al., 1991; Maheras and Kutiel, 1999; Domonkos, 2001; Founda et al., 2004; Bartzokas and Houssos, 2005), although changes recorded on other climato-

logical parameters, in many cases, appear equally significant. Moreover, the consequences of changes on other parameters on human life may be much more serious. For example, extreme precipitation events, apart from problems in transportation and communication, frequently cause severe damages in urban as well as in rural areas. Many researchers, using various methodologies, have carried out numerous studies on Mediterranean precipitation. They are targeted either on its long term changes or on the atmospheric circulation favouring high or low precipitation events. Some of them use numerical models of weather prediction while others are based on synoptic or statistical approaches (Metaxas et al., 1993; Romero et al., 1998; Jansa et al., 2000, 2001; Kutiel et al., 2001; Xoplaki et al., 2004; Cislighi et al., 2005; Kostopoulou and Jones, 2005; Tolika and Maheras, 2005). This study aims to present a detailed analysis of the extreme rainfall events in NW Greece, the wettest area of the country, which, in average, receives around 1200 mm of rainfall per year. At first, the general characteristics of the extreme precipitation events in NW Greece are given and then, by using the multivariate statistical methods of Factor Analysis (FA) and Cluster Analysis (CA) the main pressure patterns associated or favouring these events in NW Greece are objectively defined.

## 2 Data collection and methodology

The dataset used consists of daily precipitation values recorded at the meteorological station of Ioannina University, located at NW Greece, for the 33-year period 1970–2002. Also, mean sea level pressure values from 10°W to 40°E and from 30°N to 60°N, at 273 grid points spaced by 2.5° in latitude and longitude are utilized (ECMWF 40 Years Reanalysis Project).

A day is defined as an “extreme precipitation day” when the precipitation depth recorded belongs to the upper 5% of the distribution of all the daily precipitation values. In the case of Ioannina, this threshold is 35 mm. The extreme

**Fig. 1.** Time series of extreme precipitation days.

precipitation days for the 33-year period are 156 and for these days the second dataset is utilized in order to construct daily sea level pressure maps covering Europe and N. Africa. Since at the meteorological station of the University observations take place once per day, at 06:00 UTC, the synoptic charts used are those of 18:00 UTC of the previous day; i.e. in the middle of the rainy 24-hour period.

Then, FA (Jolliffe, 1986; Manly, 1986) is applied on the 273 pressure time-series, in order to reduce the dimensionality of the 156x273 data matrix. By using the limit of 85% of the total variance, the original data matrix is reduced to 156x5. Thus, “noise” is also reduced and each precipitation day is associated with 5 factors only (in fact, pressure values over Europe and N. Africa), the main contributors of precipitation in NW Greece. Since, in this work, FA is used as an intermediate tool only, FA results are not presented. Then, CA, K-means (Sharma, 1996), is applied on the factor scores time series in order to group objectively days with similar spatial pressure distribution. For the optimum number of clusters numerous test analyses were carried out. Taking also into account the seasonal distribution of the days of each cluster, eventually 11 clusters were retained. For each cluster of days, the mean value of the precipitation recorded is calculated and finally, the mean sea level pressure map is constructed, revealing the main pressure patterns, which favour extreme precipitation events in NW Greece.

It is noted that the classification of the extreme precipitation days in groups characterized by a specific spatial pressure distribution could be also performed by using FA only on the transposed data matrix (T-mode). However, in the FA classifications, the position of the pressure systems appears to play the major role and not their intensity. In this case, it will be seen that cases of similar patterns but with deeper lows or stronger highs, are found as separated categories.

The two methods, FA and CA, are briefly described in the following:

FA describes a set of  $p$  correlated variables  $X_1, X_2, \dots, X_p$  in terms of a smaller number of new uncorrelated indices, elucidating the relationship between the original  $p$  variables. Each of the  $p$  initial variables can be expressed as a linear function of  $m$  ( $m < p$ ) factors, i.e.  $X_i = a_{i1}F_1 + a_{i2}F_2 + \dots + a_{im}F_m$ , where  $F_1, F_2, \dots, F_m$  are the

factors and  $a_{i1}, a_{i2}, \dots, a_{im}$  are the factor loadings which, given that the original time series are standardized, express the correlation between the initial variables and the new ones (factors). The number  $m$  of the retained factors has to be decided, by using various rules and considering the physical interpretation of the results. A widely used process is the “rotation of the axes”, which, by maximizing some factor loadings and minimizing some others, succeeds in a better separation among the initial variables and thus in a better interpretation of the results (Richman, 1986). In this work, Varimax rotation has been applied.

CA groups objectively cases with similar characteristics. Each case (day) corresponds to a point in the  $m$ -dimensional space and each Cluster consists of those cases, which are “close” to each other in this space. The characterization of a distance between two observations  $k$  and  $l$  as “close” or “far” is determined by the squared Euclidean distance shown in Eq. (1),

$$D_{kl}^2 = \sum_{n=1}^m (x_{kn} - x_{ln})^2 \quad (1)$$

where,  $x_{kn}$  is the value of  $n$ th Factor for the  $k$ th day and  $x_{ln}$  is the value of  $n$ th Factor for the  $l$ th day. There are two main clustering techniques: the hierarchical and the nonhierarchical one. Their basic difference is that in the nonhierarchical technique the number of Clusters must be known a priori. On the contrary, in the hierarchical technique the ultimate number of Clusters is determined by a variety of statistical criteria. In this work, at first, the hierarchical technique was applied experimentally as a guide and then, the nonhierarchical K-means technique for a specific number of Clusters was used.

### 3 Results and discussion

#### 3.1 General characteristics

The average precipitation depth per extreme precipitation day is approximately 48 mm and the number of extreme precipitation days per year is approximately 5. However, during the study period, certain fluctuations have been recorded, most of them associated with atmospheric circulation changes in the Mediterranean. In Fig. 1 it is seen that the frequency of the extreme precipitation days appears reduced around 1990 when a high positive North Atlantic Oscillation (NAO) index (WMO, 1998) was recorded. The extension of the subtropical anticyclone of the Atlantic (Azores) up to central Mediterranean modified the tracks of the travelling depressions affecting precipitation in NW Greece. During this period, low pressure systems approached Greece mainly from the North, causing dry katabatic winds in NW Greece due to the NW-SE orientation of the Pindus mountain range. The decline of precipitation over major regions of the Mediterranean basin (mainly in the western part) and its association with the high positive NAO index has been found and explained by many researchers (see e.g. Hurrell,

**Fig. 2.** Monthly distribution of the extreme precipitation days (1970–2002).

**Fig. 3.** Frequency distribution of extreme precipitation days.

1995; Piervitali et al., 1997; Trigo et al., 2002). Furthermore, Krichak and Alpert (2005) related this decline also to the East Atlantic Western Russia (EAWR) pattern. In contrast to the early 1990's situation, in late 1970's, when the NAO index was negative, high frequency of extreme precipitation days is recorded. In the recent years, the occurrences of extreme precipitation events appear around normal again (the years 2003 and 2004 are included in Fig. 1 though they are not considered in the following FA and CA analyses). The correlation coefficient between the above time series and the winter NAO index was found  $-0.35$ . However, it has to be noted that Alpert et al. (2002), who examined daily rainfall categories for the Mediterranean, showed that in Spain and Italy, in spite the decrease in the total rainfall, torrential rainfall has increased significantly. This “paradox” is not detected in the eastern Mediterranean. The application of the Mann-Kendall test of randomness against trend showed that there is no statistically significant linear trend at 0.05 confidence level.

The monthly distribution of the number of extreme precipitation days, for the 33-year period, is presented in Fig. 2. It is seen that the maximum frequency appears in November and December while the minimum in summer, in accordance with the intra-annual variation of the total precipitation depths (Bartzokas et al., 2003a). The secondary maximum in May can be attributed to local afternoon thermal showers. During this period of the year depressions appear mostly in the upper levels of the atmosphere, causing insta-

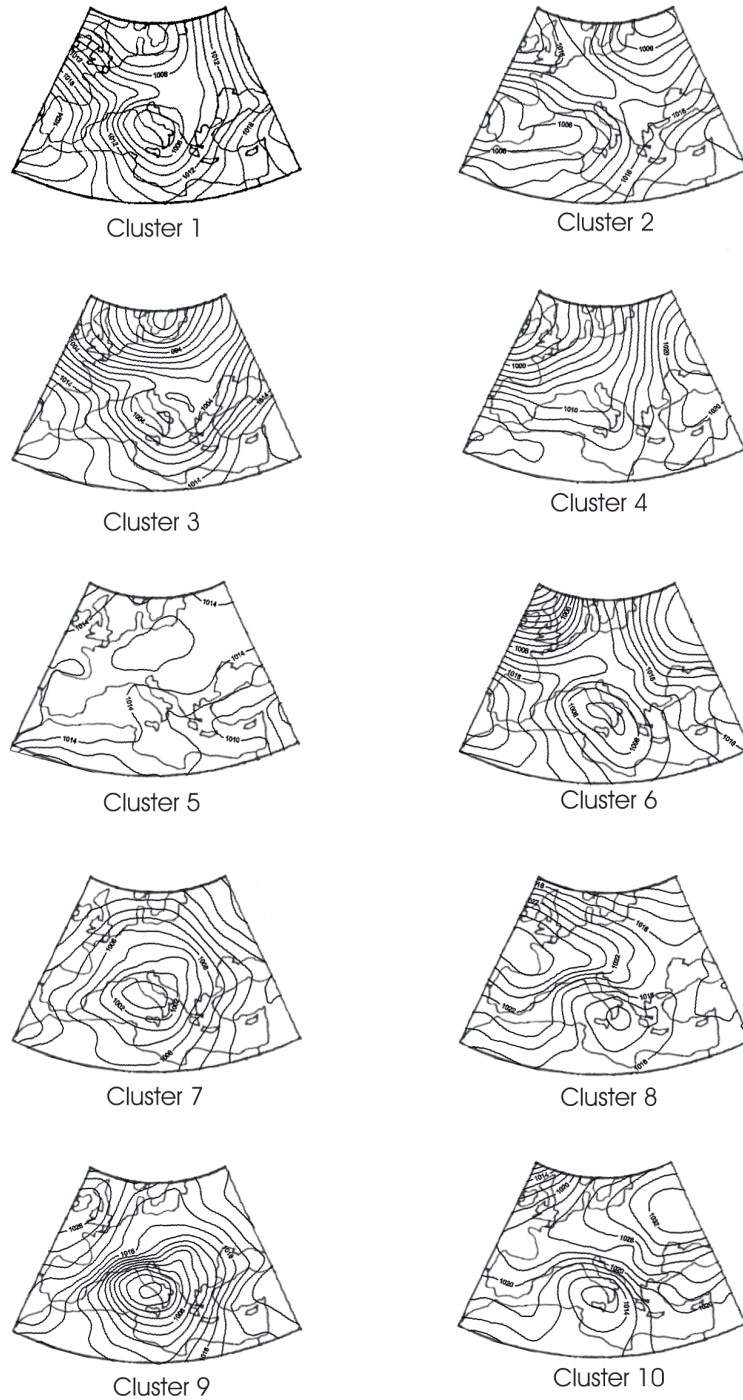

**Fig. 5.** Average precipitation (mm) per cluster.

**Fig. 6.** Seasonal distribution of extreme precipitation days.

bility due to the associated cold air masses aloft. At the surface, strong sea breeze systems prevail, causing convergence lines inland and enriching further the atmosphere with moisture (Metaxas, 1978). This maximum coincides with that detected by Metaxas (1972) for thunderstorm frequency over the same area.

The frequency distribution of the extreme precipitation days (Fig. 3) exhibits higher number of occurrences in the relatively low precipitation values, as was expected. Various studies have been carried out on frequency distributions of extreme precipitation. In most cases the Gamma distribution is considered to be the most suitable (see e.g. Ding, 1992) nevertheless in some studies the Fréchet or the Inverse Gaussian distributions appear better (see e.g. Tzavelas et al., 2005).

**Fig. 7.** The main pressure patterns favouring extreme precipitation events in NW Greece.

### 3.2 Cluster analysis results

Cluster analysis classified the 156 extreme precipitation days in 11 clusters. All the extreme precipitation cases (number of days and precipitation depths) are presented per cluster in Fig. 4. The average precipitation depth per cluster varies from 44 to 58 mm (Fig. 5). In Fig. 6 the frequency of occurrences of extreme precipitation events is shown per cluster and per season.

The mean pressure pattern of the days classified in each cluster is shown in Fig. 7. The main characteristics of these patterns are the following.

- Cluster 1: a low pressure system is located over Italy, causing southwesterly flow over NW Greece. It is encountered during winter and autumn (Fig. 6). Most of the 20 cases of this cluster are observed during the negative NAO index periods (figure not shown), as was expected.

- Cluster 2: a trough is extended eastwards from the Atlantic Ocean up to the Ionian Sea. This situation is mainly encountered in winter.
- Cluster 3: a low pressure system is located over the Adriatic Sea and the Balkans causing, in average, the second highest precipitation depth, 51 mm, in NW Greece. In this cluster belongs the pressure pattern, which produced the absolutely highest rainfall in Ioannina, 93 mm (4–5/2/1979) in the study period (Fig. 4). This situation is also a feature of winter and autumn.
- Cluster 4: a trough is extended southeastwards up to the central Mediterranean.
- Cluster 5: this is the only pattern encountered during the warm period of the year. The thermal low pressure system of SW Asia, a feature of summer, is extended up to the central Mediterranean and the subtropical anticyclone of the Atlantic (Azores) appears weaker and shrunk. Thus, the cyclonic circulation over Greece along with local atmospheric instability gives high precipitation depths in Ioannina (in average 44 mm), which however, in average, are lower than in the winter cases (Fig. 5).
- Cluster 6: an isolated low pressure system over southern Italy, causing southerly flow over NW Greece; mainly in autumn.
- Cluster 7: an extended low pressure system covers the whole Europe mainly during autumn and spring.
- Cluster 8: a shallow depression over the Ionian Sea; mainly a feature of autumn.
- Cluster 9: the pressure system located over Italy is the deepest one producing the highest amounts of rainfall in NW Greece in winter and autumn. In this cluster, the 7 out of the 11 cases cause rainfall depths above 60 mm (Fig. 4) while the average value is 58 mm. The difference in the mean precipitation value between this cluster and the clusters 1, 5, 7, 8 is found statistically significant at 0.05 level.
- Cluster 10: a strong pressure gradient over western Balkans due to a depression over southern Italy and an anticyclone over western Russia, causes southerly flow over NW Greece with high amounts of rainfall in all seasons except in summer.
- Cluster 11: this cluster comprises 1 day only (3/12/1976) with a unique pressure pattern (a low pressure system covers the whole Europe). Test analyses with different number of clusters showed that its unique pressure pattern could not be classified in any other cluster (figure not shown).

#### 4 Conclusions

The extreme precipitation events in NW Greece were studied by using daily rainfall values from the meteorological station of Ioannina University. It was found that the 156 extreme precipitation days could be classified in 11 clusters with common spatial distribution of atmospheric pressure over Europe and the Mediterranean. For each cluster of days the mean pressure pattern was constructed and it was found that seven of the patterns are encountered in winter and autumn, three of them cover a period from middle autumn to middle spring and one is a feature of the warm period of the year. As was expected, in most of them the cause of the extreme precipitation event is a low pressure system located west of Greece in accordance with the findings of Bartzokas et al. (2003b). Its position and its intensity differ considerably from pattern to pattern. In most cases, the depression is found to be located either in the Ionian Sea or over Italy and it is either connected to higher latitude circulation or it appears as an isolated cyclone. In some cases the whole Europe and the Mediterranean are covered by an extended low pressure system or a trough. In the single summer pattern rainfall is caused by an extension of the SW Asia thermal low towards the central Mediterranean.
